Abstract

Given a finite point set X in the plane, the degree of a pair $\{x, y\} \subset X$ is the number of *empty triangles* $t = \text{conv}\{x, y, z\}$, where empty means $t \cap X = \{x, y, z\}$. Define $\deg X$ as the maximal degree of a pair in X . Our main result is that if X is a random sample of n independent and uniform points from a fixed convex body, then $\deg X \geq cn/\ln n$ in expectation.

Keywords: Finite point sets in the plane, empty triangles, random samples

1 Introduction

Let X be a finite set of points in \mathbb{R}^2 in general position meaning that no 3 points of X are collinear. For $k \geq 2$, let $\binom{X}{k}$ be the family of all k -element subsets of X . The triangle $t := \text{conv}\{x_1, x_2, x_3\}$ where $\{x_1, x_2, x_3\} \in \binom{X}{3}$ is said to be empty (in X) if $t \cap X = \{x_1, x_2, x_3\}$.

The degree of a pair $\{x, y\} \in \binom{X}{2}$ is the number of $z \in X$ such that $\{x, y, z\} \in \binom{X}{3}$ determines an empty triangle. The degree of $\{x, y\}$ will be denoted by $\deg(x, y)$ or $\deg(x, y; X)$. We set

$$\deg X = \max \left\{ \deg(x, y) : \{x, y\} \in \binom{X}{2} \right\}.$$

Setting $|X| = n$ we clearly have $\deg X \leq n - 2$. The following conjectures was raised by the first author, and appeared first in a paper of Paul Erdős [4] in 1992 and repeated in [2].

Conjecture 1. $\deg X$ goes to infinity as $n \rightarrow \infty$.

Very little is known about the validity of the conjecture. Namely, it is shown in [2] that $\deg X \geq 10$ for large enough n . The construction in [3] gives a set $X \in \mathbb{R}^2$ in general position with $\deg X = 4\sqrt{n}(1+o(1))$, as one can check easily.

In this paper we give a lower bound on $\deg X$ in a special case, namely, when $X = \xi_n$ is a set of n independent, random points chosen uniformly from a fixed compact convex set $C \subset \mathbb{R}^2$ that has nonempty interior. Then ξ_n is in general position with probability one, so $\deg \xi_n$ is a well-defined random variable. Our main result shows that the expectation of $\deg \xi_n$ is quite close to n .

Theorem 1. *There is a universal constant $c > 0$ such that*

$$\mathbb{E}(\deg \xi_n) \geq \frac{cn}{\ln n}.$$

The following theorem is not a consequence of the previous one, even though it seems weaker.

Theorem 2.

$$\deg \xi_n \xrightarrow[n]{(proba.)} +\infty.$$

Although Theorem 2 can be proved by a modification of the argument used for Theorem 1 we provide an independent proof relying on a “local argument” that can be used quite generally. This local argument is the following. Take a grid with mesh $1/\sqrt{n}$ on the plane. This grid defines certain squares, and each square Q which is totally included in the underlying convex body C contains a $\text{Binomial}(n, 1/n)$ number N_Q of points of ξ_n . When n is large, N_Q can be approximated by a Poisson random variable with parameter 1. Even if these variables N_Q are not independent, some results can be transferred from the case where they are (this is in substance Lemma 6). Then, using a collection of “ n independent squares”, each of them containing Poisson(1) number of random points, it is not difficult to see that one of these squares will contain a set Y of k points satisfying $\deg Y = k - 2$, with probability going to 1, since the probability that one of them satisfies this condition is positive (see details in the proof of Theorem 2, below).

This local argument gives the following more general statement concerning “order types” [6]. Two finite sets $A, B \subset \mathbb{R}^2$ are of *same type* if both are in general position and there is a one-to-one correspondence between A and B , say $a_i \leftrightarrow b_i$ ($i = 1, \dots, k$) where $A = \{a_1, \dots, a_k\}$ and $B = \{b_1, \dots, b_k\}$, such that the orientations of the triangles (a_h, a_i, a_j) and (b_h, b_i, b_j) are the same for all $1 \leq h < i < j \leq k$. Being of the same type is an equivalence relations and equivalence classes are called *order types*.

Theorem 3. *Let P be a fixed order type. Then, as $n \rightarrow \infty$,*

$$\mathbb{P}(\xi_n \cap Q \text{ is of type } P \text{ for some square } Q) \rightarrow 1.$$

The proof goes the same way as that of Theorem 2 and is therefore omitted.

We close this section by stating (or rather repeating) another conjecture from [2]. Given a finite $X \in \mathbb{R}^2$ in general position, let $f(X)$ denote the number of empty triangles in X . Set

$$f(n) = \min\{f(X) : X \subset \mathbb{R}^2 \text{ is in general position and } |X| = n\}.$$

It is known that

$$n^2 - 5n \leq f(n) \leq 1.6195 \dots n^2$$

where the lower bound is from [5] and the upper one from [3]. We think that the lower bound is larger than n^2 . We state the following

Conjecture 2. For large enough n , $f(n) > 1.01n^2$.

The same conjecture appears also in [2]. Note that, when ξ_n is the random uniform sample from C , the expectation of $f(\xi_n)$ is of order $2n^2$, see Valtr [9].

2 Proof of Theorem 1

The proof relies of a first moment argument that we state for arbitrary X first. For any $T > 0$, any set X , we have

$$\sum_{\{x,y\} \in \binom{X}{2}} \mathbb{1}(\|x - y\| \leq T) \deg(x, y; X) \leq N_T(X) \deg X \quad (2.1)$$

where

$$N_T(X) = \sum_{\{x,y\} \in \binom{X}{2}} \mathbf{1}(\|x - y\| \leq T)$$

is the number of pairs $\{x, y\} \in \binom{X}{2}$ with $\|x - y\| \leq T$. From (2.1), we get the following formula which will play a central role here:

$$\deg X \geq \frac{1}{N_T(X)} \sum_{\{x,y\} \in \binom{X}{2}} \mathbf{1}(\|x - y\| \leq T) \deg(x, y). \quad (2.2)$$

A comment must be added here : when $N_T(X) = 0$, the division by $N_T(X)$ is not valid in (2.2). Notice however that in this case $\sum_{\{x,y\} \in \binom{X}{2}} \mathbf{1}(\|x - y\| \leq T) \deg(x, y; X)$ is also 0, and then the right hand side in (2.2) has the form 0/0. Thus in this case we consider this ratio to be 0, and then (2.2) is indeed valid (the problem disappears in (2.4)).

We need some geometric preparations. Clearly $\deg X$ is invariant under non-degenerate affine transformation (and so is $f(X)$). Also, ξ_n is invariant (or rather equivariant) under such a transformation. So we can apply an arbitrary (non-degenerate) transformation to C , and $\mathbb{E} \deg \xi_n$ will not change. By the Löwner half of the Löwner-John theorem (see for instance [7], or [1] for a more modern treatment), there is a pair of concentric ellipses E_1, E_2 so that E_2 is a blown up copy of E_1 by a factor of 2 with $E_1 \subset C \subset E_2$. First we apply the affine transformation so that the area of C becomes equal to one. This is convenient since then the Lebesgue measure coincides with the probability measure defining ξ_n . Second we apply an area preserving affine transformation that carries E_1 resp. E_2 to rD and $2rD$ where D the Euclidean unit disk, centered at the origin. It is easy to see that one can take $r = 27^{-1/4}$. From now on we assume that C is in this position, and $rD \subset C \subset 2rD$.

We can put now $X = \xi_n$ in (2.2) and take the expectation on both sides. This yields

$$\mathbb{E}(\deg \xi_n) \geq \mathbb{E} \left(\frac{1}{N_T(\xi_n)} \sum_{\{x,y\} \in \binom{\xi_n}{2}} \mathbf{1}(\|x - y\| \leq T) \deg(x, y; \xi_n) \right), \quad (2.3)$$

and further, for any $K > 0$,

$$\mathbb{E}(\deg \xi_n) \geq \frac{1}{K} \mathbb{E} \left[\sum_{x,y \in \binom{\xi_n}{2}} \mathbf{1}(\|x - y\| \leq T) \deg(x, y; \xi_n) \mathbf{1}(N_T(\xi_n) \leq K) \right]. \quad (2.4)$$

The idea now is to somehow optimise in $T = T_n$ and in $K = K_n$. The intuition here is that in the random case $\deg \xi_n$ will be reached for a pair $\{x, y\}$ with x, y very close. The best we can do here is to take $T = 1/n$ and $K = c \ln n$ for some $c > 0$ to be fixed later.

Remark. The closest pair in $\binom{\xi_n}{2}$ will have distance approximately n^{-1} and we expect the closest pair of points in ξ_n to be very likely to give the maximal, or close to the maximal degree. In fact, for $T := T_n \rightarrow 0$, it is a well known fact (see, e.g., the recent paper by Reitzner, Schulte, and Thaele [8]) that

$$\mathbb{E}(N_T(\xi_n)) \approx \frac{\pi}{2} n^2 T^2 (1 + o(1))$$

implying that the expected number of pairs of distance n^{-1} is positive.

Before choosing these special values for T and K , we go on from (2.4) by starting the computation of the right hand side, to be denoted by RHS from now on. By conditioning successively on each pair $\{x_i, x_j\}$ of $\binom{\xi_n}{2}$, we have

$$\text{RHS} = \frac{\binom{n}{2}}{K} \int_{C^2} \mathbf{1}(\|x - y\| \leq T) \mathbb{E}[\deg(x, y; \xi_{n-2}) \mathbf{1}(N_T(\xi_{n-2} \cup \{x, y\}) \leq K)] dy dx, \quad (2.5)$$

here $\deg(x, y; \xi_{n-2})$ denotes the number of empty triangles with base $\{x, y\}$ in $\zeta := \xi_{n-2} \cup \{x, y\}$.
Since

$$\mathbb{E}(X\mathbf{1}(A)) = \mathbb{E}(X) - \mathbb{E}(X\mathbf{1}(A^c))$$

we have the following bound on the factor in (2.5)

$$\begin{aligned} \mathbb{E}[\deg(x, y; \xi_{n-2})\mathbf{1}(N_T(\zeta) \leq K)] &= \mathbb{E}[\deg(x, y; \xi_{n-2})] - \mathbb{E}[\deg(x, y; \xi_{n-2})\mathbf{1}(N_T(\zeta) > K)] \\ &\geq \mathbb{E}[\deg(x, y; \xi_{n-2})] - \mathbb{E}[n\mathbf{1}(N_T(\zeta) \geq K)]. \end{aligned} \quad (2.6)$$

Choose now $\rho = r/2$. Then the disk ρD is contained in $rD \subset C$ and every point of ρD is farther than $\rho = r/2$ from the boundary of C .

Lemma 4. *If $\|x - y\| \leq T = T_n := n^{-1}$, and $x, y \in \rho D$, then $\mathbb{E}[\deg(x, y; \xi_{n-2})] \geq \rho n(1 - e^{-\rho/2})$.*

We need one more ingredient, actually a crucial one, which is a special case of Theorem 5.3 from [8].

Lemma 5. *Assume $\alpha > 0$ and $T = \alpha n^{-1}$. Then there is $c = c(\alpha) > 0$ such that*

$$\mathbb{P}(N_T(\xi_n) \geq 144 \ln n) \leq cn^{-3}.$$

Assuming for a moment that Lemma 4 has been proved, we finish the proof of Theorem 1. Note first that

$$\mathbb{E}[n\mathbf{1}(N_T(\zeta) \geq K)] = n\mathbb{P}[N_T(\zeta) \geq K]. \quad (2.7)$$

Further, let $D(x, T)$ and $D(y, T)$ denote the disks centered at x and y with radius T . Then

$$N_T(\zeta) \leq N_T(\xi_{n-2}) + |\xi_{n-2} \cap D(x, T)| + |\xi_{n-2} \cap D(y, T)| + 1 \leq N_T(\xi_{n-2}) + 2N_{2T}(\xi_{n-2}) + 1 \leq 3N_{2T}(\xi_n) + 1$$

where we used the fact that if two points lie in $D(x, T)$, then their distance is at most $2T$. This implies, with $K = K_n = 3 \cdot 145 \ln n$, that

$$\mathbb{P}[N_T(\zeta) \geq K_n] \leq \mathbb{P}[3N_{2T}(\xi_n) + 1 \geq K_n] \leq \mathbb{P}[N_{2T}(\xi_n) \geq 144 \ln n].$$

We set $T = T_n = 1/n$. Then, using Lemma 5 with $\alpha = 2$, we have with a suitable $c > 0$

$$\mathbb{E}[n\mathbf{1}(N_{T_n}(\xi_{n-2}) \geq K_n)] \leq n\mathbb{P}[N_{2T_n}(\xi_n) \geq 144 \ln n] \leq cn^{-2}.$$

Hence we see that the second term in (2.6) is negligible compared to the first one, whose value is more than $n\rho(1 - e^{-\rho/2}) > 0.086n$, by Lemma 4, for n large enough.

Plugging what is known into (2.6), we obtain

$$\text{RHS} \geq \frac{n(n-1)}{2K_n} \left(n\rho(1 - e^{-\rho/2}) - o(1) \right) \int_{(\rho D)^2} \mathbf{1}(\|x - y\| \leq T_n) dx dy.$$

The value of the integral being larger than c'/n^2 for some c' (in fact, it is equivalent to $\pi\rho^2 T_n^2$), since K_n is constant times $\ln n$, this ends the proof of Theorem 1. \square

Lemma 4 remains to be proved.

Proof of Lemma 4. Fix x and y in ρD with $\|x - y\| \leq 1/n$. We have

$$\begin{aligned} \mathbb{E}[\deg(x, y; \xi_{n-2})] &= \mathbb{E} \left[\sum_{z \in \xi_{n-2}} \mathbf{1}(\xi_{n-2} \cap \text{conv}\{x, y, z\} = \{x, y, z\}) \right] \\ &= (n-2)\mathbb{P}(\xi_{n-3} \cap \text{conv}\{x, y, U\} = \{x, y, U\}) \end{aligned}$$

where U is a random variable uniform in C independent from ξ_{n-2} . This gives

$$\mathbb{E}[\deg(x, y; \xi_{n-2})] = (n-2) \int_C (1 - A(x, y, u))^{n-3} du.$$

where $A(x, y, u)$ is the area of the triangle x, y, u . (This is where the condition that the area of C is one is convenient.) Let $Q(x, y)$ be the square of side length ρ , centered at $(x + y)/2 \in \rho D$, with one side parallel with the vector $x - y$. Instead of integrating (with respect to u) on C , we integrate only on the square $Q(x, y)$. This gives the lower bound:

$$\begin{aligned} \int_C (1 - A(x, y, u))^{n-3} du &\geq \int_{Q(x, y)} (1 - A(x, y, u))^{n-3} du \\ &\geq \int_{[0, \rho]} \int_{[0, \rho]} (1 - \frac{1}{2} \|y - x\| z_2)^{n-3} dz_2 dz_1 \\ &= \rho \frac{2}{\|x - y\|} \int_{[0, \|x - y\| \rho / 2]} (1 - t)^{n-3} dt \\ &= \frac{2\rho}{\|x - y\|} \frac{1}{n-2} [1 - (1 - \|x - y\| \rho / 2)^{n-2}] \\ &\geq \frac{2\rho n}{n-2} [1 - (1 - \rho / (2n))^{n-2}] \\ &\geq \frac{2\rho n}{n-2} [1 - e^{-(n-2)\rho / (2n)}] \geq \frac{\rho n}{n-2} (1 - e^{-\rho/2}) \end{aligned}$$

for n large enough. The last inequality is a consequence of $[1 - e^{-(n-2)\rho / (2n)}] \rightarrow 1 - e^{-\rho/2}$. \square

3 Proof of Theorem 2

Consider the convex body C and ξ_n as defined at the beginning of the paper (we don't need the disks $rD, 2rD$ now). Add a grid with mesh $1/\sqrt{n}$ on the plane. The squares $(Q_i, i \in I)$ hence obtained have area $1/n$. For n large enough (that we choose even, for convenience), choose $n/2$ squares $Q_1, \dots, Q_{n/2}$ totally included in C , and consider $C^* = C \setminus \cup_{i=1}^{n/2} Q_i$ be the remaining part of C .

For $1 \leq i \leq n/2$, let $\xi_n^{(i)} = \xi_n \cap Q_i$, and set $\xi_n^* = \xi_n \cap C^*$ the "composition" of the square of interests and the other ones. Further, let $N_i = |\xi_n^{(i)}|$, and let $N^* = |\xi_n \cap C^*|$.

The family $(N_1, \dots, N_{n/2}, N^*)$ has multinomial distribution $\text{Mult}(1/n, \dots, 1/n, 1/2)$. As such it is distributed as a collection of independent Poisson random variables $(P_1, \dots, P_{n/2}, P^*)$ conditioned by $P^* + \sum_{i=1}^{n/2} P_i = n$, where the P_i 's are $\text{Poisson}(1)$ distributed and P^* is $\text{Poisson}(n/2)$.

We first claim that rare events for Poisson random variables $(P_1, \dots, P_{n/2})$ are also rare events for the first $n/2$ marginals $(P_1, \dots, P_{n/2}, P^*)$ conditioned by $P^* + \sum_{i=1}^{n/2} P_i = n$.

Lemma 6. *There exists a constant $b > 0$, such that for large enough n and for any measurable set $A \in \mathbb{R}^{n/2}$,*

$$\mathbb{P} \left((P_i, i = 1, \dots, n/2) \in A \mid P^* + \sum_{i=1}^{n/2} P_i = n \right) \leq b \mathbb{P}((P_i, i = 1, \dots, n/2) \in A). \quad (3.8)$$

Proof. Take any $m_1, \dots, m_{n/2} \in \mathbb{N}$ and write

$$\mathbb{P} \left(P_i = m_i, i = 1, \dots, n/2 \mid P^* + \sum_{i=1}^{n/2} P_i = n \right) = \mathbb{P}(P_i = m_i, i = 1, \dots, n/2) \frac{\mathbb{P}(P^* = n - \sum_{i=1}^{n/2} m_i)}{\mathbb{P}(P^* + \sum_{i=1}^{n/2} P_i = n)}.$$

By Stirling, $\mathbb{P}\left(P^\star + \sum_{i=1}^{n/2} P_i = n\right) \sim 1/\sqrt{2\pi n}$, and at the numerator, it is easily checked that $\mathbb{P}(P^\star = n - \sum_{i=1}^n m_i) \leq \max_k \mathbb{P}(P^\star = k) = O(1/\sqrt{n})$, which ends the proof. \square

We now consider the same collection of $M = n/2$ squares Q_1, \dots, Q_M as above, but in each of them we place independently of the other ones, a Poisson point process $\zeta^{(j)}$ with intensity 1. Here $P(j) := |\zeta^{(j)}| \sim \text{Poisson}(1)$, and conditionally on $P(j) = k$, the k points in $\zeta^{(j)}$ are taken in Q_j according to the uniform distribution.

A simple application of the Lemma and of the fact that for both models the points in the squares are i.i.d. uniform (and independent of the other squares) given their numbers, we get that for any large enough n and for any measurable set A

$$\mathbb{P}((\xi_n^{(i)}, i = 1, \dots, n/2) \in A) \leq b \mathbb{P}((\zeta^{(i)}, i = 1, \dots, n/2) \in A),$$

with the same constant b as in the Lemma.

In the Poisson model we have more independence, and it is then more easy. The number of squares Q_j such that $P(j) = k$ is $\text{Binomial}(M, e^{-1}/k!)$ distributed. Let ξ_k be a random, independent sample of k points chosen uniformly from the unit square, and set $p_k = \mathbb{P}(\deg \xi_k = k - 2)$. Clearly $p_k > 0$: for instance if the k points are in a convex position (which happens with positive probability), then all triangles formed with 3 different points are empty.

It follows that the number of squares Q_j such that $P(j) = k$ and $\deg(\zeta^{(j)}) = k - 2$ has law $\text{Binomial}(M, (e^{-1}/k!)p_k)$. When M goes to $+\infty$, at least one of these squares satisfies $P(j) = k$ and $\deg(\zeta^{(j)}) = k - 2$ with probability going to 1. This implies that for any L , letting

$$B_L := \{\forall l \leq L, \exists j : P(j) = l, \deg(\zeta^{(j)}) = l - 2\}$$

we have

$$\mathbb{P}(B_L) \rightarrow 1.$$

The probability of the complementary event $A = \mathbb{C}B_L$ goes to 0. Lemma 6 allows then to see that

$$\mathbb{P}\left((P_i, i = 1, \dots, n/2) \in A \mid P^\star + \sum_{i=1}^{n/2} P_i = n\right) \rightarrow 0$$

which concludes the proof of Theorem 2. \square
